

PART I

Chapter 3

Economic Benefits of Climate Action: The Urban Dimension

This chapter examines the benefits of implementing urban policies to tackle climate change. Findings from a computable general equilibrium model (IMACLIM-R) that incorporates an urban module and data from the OECD Metropolitan Database demonstrate that the traditionally perceived trade-off between economic growth and achieving mitigation objectives (observed at a macroeconomic level) can be alleviated when urban policies are introduced. Under a policy scenario where national emission reduction strategies are implemented, aggregate mitigation costs can be reduced if economy-wide environmental policies are complemented by urban policies, such as congestion charges or increasing spatial density. This is due to complementarities with other policy objectives, such as lower local pollution and health benefits, and enhancement of city attractiveness and competitiveness through lower local pollution levels. The chapter also discusses other types of local benefits of climate change policies, including quality of life, increased efficiency, energy security, and infrastructure improvements.

Key points

Urban policy can contribute to least-cost national CO₂ emissions reduction targets and mitigation strategies

- Findings from a computerised general equilibrium model (IMACLIM-R) with an urban module demonstrate that urban policies can lead to a reduction of total OECD global energy demand and, consequently, of CO₂ emissions at relatively low cost.
- Under a policy scenario where national emission reduction objectives are implemented, the aggregate mitigation costs can be reduced if economy-wide environmental policies are complemented by urban policies, such as congestion charges or increasing spatial density.
- The lower tradeoffs between economic growth and environmental priorities at the urban level may be due to complementarities of policies observed only at the local scale.

The costs of delaying action on climate change may be high, while some urban climate policies may be “no-regret” policies

- While climate change mitigation and adaptation policies require significant investment, delaying action can increase future costs and limit future options for adapting to climate change impacts or reducing emissions in cities.
- Beyond direct costs of climate change in urban centres, the economic impacts of climate change can have positive rebound effects in the job market and reduce tax revenue.
- Some urban climate policies may be no-regret policies as they can provide co-benefits that offset their cost. These include public health benefits, cost savings from reduced energy use and increased efficiency, energy security, and improved urban quality of life. These additional non-climate benefits may also help to explain the lower tradeoffs and synergies between economic growth and greenhouse gas emissions reduction at the metropolitan level.

Simultaneously addressing stabilisation of the climate and economic growth has become a challenging task for the international policy community. This apparent trade-off has been so far discussed in two ways. The first is to measure economic growth in a way that integrates the degradation of environmental assets into the calculation of GDP. The second is to take into account the discounted long-term economic benefits of climate stabilisation, by avoiding extreme future adverse events. Both approaches entail significant measurement and valuation problems. However, findings from a regional growth model disaggregated at the metropolitan level, presented in this chapter, show that the trade-off between economic growth and climate policy can actually be lower when local dimensions are taken into account. Namely, policies to reduce traffic congestion and increase urban density can have a significant effect on national GHG emissions levels while allowing the local economy to grow. Also, adaptation and mitigation policies can provide important benefits in the form of reduced energy costs, increased local energy security and improved

urban health. This is particularly important for city and regional governments, which can be sensitive to immediate price increases and investment costs in exchange for the less-tangible and longer-term benefits of addressing global climate change.

Effects of urban policies on global energy demand and carbon emissions

A Computable General Equilibrium (CGE) model has been used to simulate a world economy divided into macro-regions in economic interaction with OECD metropolitan areas. More precisely, this modelling exercise has been carried out by employing the spatialised version of the IMACLIM-R CGE framework (Crassous *et al.*, 2006). IMACLIM-R allows simulating the interactions between changes in energy consumption, carbon emissions and economic growth, given a set of policies and other exogenous factors (Box 3.1).¹ Two types of urban policies are explicitly explored: i) urban densification;² and ii) congestion charges (see also Chapter 9). The results suggest that densification policies would increase people's propensity to use public transport, from 12.9% in the baseline scenario to 14% by 2050 with densification policies. As a consequence, the volume of private transport falls across the

Box 3.1. A CGE model of metropolitan economies

The impact on climate change of policies at the metro-regional scale can be modelled using a general equilibrium approach that takes into account most of the factors that influence the way in which an economic system works. In particular, computable general equilibrium (CGE) models can be used in order to simulate a world economy divided into countries and groups of countries, multiple sectors, and production and consumption functions. The approach taken in this chapter involves the use of IMACLIM-R model (Crassous *et al.*, 2006; see Annex 3.A1 for details). The global CGE model employed in this chapter has been enriched by a metropolitan module representing the metropolitan economies and their interactions with the macro-level (Grazi and Waisman, 2009). This module was calibrated on the OECD *Metropolitan Database* and is consistent with the assumptions in the OECD ENV-Linkages model.

The model is based on the comparison of two scenarios: one without policy changes, the so-called *baseline scenario* (BS), and a *climate policy scenario*. The comparison of these two scenarios for each period enables quantification of the magnitude of the policies' impact. Two particular local policies have been tested to explore possible impacts on the economy and on carbon emissions: densification policies and congestion charges. The densification policy can be interpreted as an indirect form of intervention whose primary effect is to reduce individuals' dependence on private transport for commuting. Densification is the increase in the number of inhabitants living in a given territorial unit, for instance, the number of inhabitants per km². In analysing where an economy chooses to locate and what determinants impacts its distribution across available agglomerations, the metropolitan module in the IMACLIM-R model draws on the new economic geography approach (Krugman, 1991). The static urban agglomeration structure is described in the model by three main determinants: locally available active population, labour productivity, and urban density. Data are taken from the *OECD Metropolitan Database*. The long-run mechanism through which firms (and people consequently) agglomerate is driven by an agglomeration-specific attractiveness index that encompasses three main factors: the rate of capital return, the expected volume of production and the change in absolute number of firms. Firms therefore are attracted by cities with higher capital returns (determined by labour productivity), an increase in the size of markets (given by the expected volume of production) and the presence of other firms (so that they can establish backward and forward linkages). The model also allows for migration of people among regions and cities following firms' investment decisions. Higher-productivity cities will be able to offer higher wages and thus attract workers and skills, which completes the agglomeration cycle. Higher wages are assumed to be a compensation for workers as they need to cope with the external costs of the agglomeration, namely commuting, housing costs and local pollution.

Figure 3.1. Energy demand with a densification policy
Per cent difference in total OECD demand (densification vis-à-vis baseline scenario)

Note: The line shows the difference between demand of energy once cities are denser and the baseline scenario (or business as usual).

StatLink  <http://dx.doi.org/10.1787/888932342335>

OECD, implying a decrease in the demand for oil. If cities were to become denser, total OECD energy demand would decrease from 2020 on, and would reach 0.6% less compared to the baseline by 2050 (Figure 3.1). This is in line with previous evidence that urban form affects individuals' travel behaviour and consequently global environmental quality (Grazi et al., 2008). A similar result is obtained if congestion charges only are applied.

Following the implementation of densification and congestion charges, carbon emissions are reduced relative to the baseline, following a similar pattern to the one of energy demand from 2020 on (Figure 3.2). We consider the introduction of a local tax on the use of private vehicles by individuals for commuting purposes. This takes the form of a toll road of the type already implemented in some metropolitan regions (London and Stockholm

Figure 3.2. Carbon emission reductions with a densification policy
Per cent difference in total emission reductions in OECD (densification vis-à-vis baseline scenario)

StatLink  <http://dx.doi.org/10.1787/888932342334>

among others).³ Revenues from the toll road tax can be used to finance metropolitan region densification plans, thereby lowering the cost of densification. The fact that many city or metropolitan governments have the capacity to implement such a tax *and* decide how revenues will be spent contributes to the effectiveness of urban-level policies. At the national level, responsibility for transportation, land-use and tax collection would likely reside in separate government institutions, *e.g.* the Ministries of Transport, Housing and Territorial Planning, and Treasuries.

Environment and economic growth at the urban scale: From trade-offs to policy complementarity

Densification and congestion charges are not the only effective tools to reduce energy demand and carbon emissions; however, they are important as it can be demonstrated that they do not have a detrimental effect on long-term economic growth.⁴ More specifically, the model generates three adjustment phases in economic growth, over time. First, an initial minor and short-lived economic expansion exists with both policies in almost the same pattern until 2025, mainly driven by lower fuel prices as demand for oil falls. Second, economic growth becomes mildly negative after 2030 (Figure 3.3). As fuel prices fall, people find it less costly to drive again and so they increase their demand for oil and prices start to rise again, bringing about a short-lived economic contraction. Finally, a more important expansion of economic activity – more so under the congestion charges scenario – becomes possible around 2038 since the new increase in oil prices tends to accelerate technical change and thus spurs innovation and economic growth.

Figure 3.3. **Economic growth with local policies**

Changes in GDP comparing densification and congestion charges vis-à-vis baseline scenario

Note: DS refers to Densification Scenario; BS refers to Baseline Scenario; TS refers to Tax Scenario (in turn refer to the application of congestion charges).

Source: Simulations from IMACLIM-R model based on the OECD Metropolitan Database.

StatLink  <http://dx.doi.org/10.1787/888932342373>

Underlying these results is the fact that technology-support policies embodied in the IMACLIM-R model can reduce and even offset the economic cost of curbing carbon emissions. In this regard, the discussion on how to address the climate change problem has mainly focused on the economic impact of carbon abatement. The latter has been

estimated at 1 to 3% – depending on the discount rate used – of reduction in world GDP (cf. Stern, 2007; OECD, 2009). However, the OECD (2009) acknowledges that the perceived trade-off between economic growth and mitigation policies is lower if technology-support policies are considered: first because technology-support policies may help address innovation failures and boost economic growth; second because these policies postpone emission cuts until technologies become available and therefore reduce the impact on economic growth (OECD, 2009).

In other words, the prospects of economic growth can actually be improved by providing incentives to innovation and growth. Emission reduction targets implied by climate policy bring about the need to improve processes and change products in a way that allow firms to comply with such regulations. Firms are then obliged to invest in improving their processes; many will fail to do so and perhaps be driven out of market, but many others may find new ways of doing things and in the long run such innovation bursts will lead to greater economic progress. OECD (2009) shows that R&D policies and technology adoption incentives are better suited than price and command-and-control (CAC) instruments for correcting specific innovation and technology diffusion failures that undermine the creation and diffusion of emissions-reducing technologies.

Assessed at the regional or local level, policies to reduce carbon emissions are less opposed to economic growth than policies designed at the aggregate level. As mentioned previously, cities are major contributors to climate change through energy demand and on-road transportation; thus local authorities can play a part in reducing such demand and emissions by inducing changes in the way people live and commute in urban areas. Moreover, policy tools at the disposal of cities' authorities are effective in tackling emissions by avoiding costs that are generally assumed at the macro level. Local policies that change commuting patterns – and there could be other policies to reduce emissions that are not explored in the model, such as building codes – can effectively reduce carbon emissions and, in the long run, boost economic growth through innovation. The reason for this lower trade-off lies in the fact that more complementarities among policies and economic activities can be observed at the local than at the aggregate or national level.

To illustrate the combined effect of climate and urban policies, an emission reduction scenario was simulated in the CGE model at 450 ppm CO₂eq (IPCC Scenario III, see Box 3.2).⁵ In terms of carbon abatement, this scenario corresponds roughly to more than a 30% reduction in world carbon emissions by 2050, compared with the baseline (from above 30 to less than 20 GtCO₂). In the OECD, the abatement is even bigger in relative terms (Figure 3.4). The associated GDP losses could represent up to one-third of a percentage point for the OECD (Table 3.1).

For the group of OECD countries, it was possible to simulate the combined effects of implementing both a carbon price and urban spatial policies. Under the 450 ppm target, the gains from urban policies are relatively mild, although positive. If a more demanding target, such as 410 ppm, were to be reached,⁶ the complementarity between the two policies would be sizeable (around 0.3% of OECD GDP, when a strong discounting rate is used). The global GDP losses under the 410 ppm climate policy scenario range from 3% to greater than 4% of GDP. Although it could not be simulated at this stage due to lack of data, it is likely that urban policies implemented at a global scale could generate much larger benefits.

Box 3.2. Emission targets and modelling of climate policy

When carbon emission targets set to avoid serious climate change (e.g. limiting global warming at 2 °C) are compared with those considered in energy economics literature on mitigation scenarios, substantial discrepancies emerge. So far, most model assessments of mitigation costs have considered stabilisation levels of atmospheric greenhouse gas concentrations above 500 ppm CO₂eq (e.g. Stern (2007) focuses on mitigation scenarios aiming at 500 to 550 ppm CO₂eq). Although such stabilisation levels are likely to be insufficient for keeping warming below 2 °C (Meinshausen, 2006), they are used as a benchmark for climate-energy modelling exercises: out of 177 mitigation scenarios considered in the IPCC AR4, only six were grouped in the lowest stabilisation category (corresponding to 445-490 ppm CO₂eq, which is consistent with a medium likelihood of achieving the 2 °C target).

The rationale behind the limited number of studies considering reduction targets that are consistent with the 2 °C target is that such low stabilisation can only be attained under a number of restrictive assumptions: i) a high degree of flexibility of substitution within the energy economic system; ii) a broad portfolio of technology options (including bioenergy, other renewables and carbon capture and storage); iii) a full and immediate participation in a global mitigation effort; and iv) the necessity of generating negative emissions.

Going beyond the alleviation of carbon abatement costs, there are complementarities between carbon emission reductions and economic growth that can be found at the urban level, for instance with regard to attractiveness. Using the attractiveness index that is at the heart of the agglomeration dynamics in the spatialised version of IMACLIM-R model, it can be seen that a group of highly attractive metropolitan regions are associated with high levels of carbon emissions stemming from commuting, such as Los Angeles, New York, Seoul, Tokyo or Toronto. In contrast, a number of metropolitan regions combine relatively low emission levels per automobile and high attractiveness (e.g. Auckland, Madrid and Sydney) (Figure 3.5). Commuting modes could therefore be at the heart of carbon emission patterns, implying that a more intensive use of public transport may contribute significantly to reducing GHG emissions and pollution while increasing local attractiveness.

In this context, low pollution and GHG emission levels will increasingly be a factor driving the attractiveness of urban areas. In the next two decades, cities that could become more attractive will do so while also curbing local pollution. According to the results of the CGE model, and if current trends are sustained, cities that could experience improvements in attractiveness by 2030 include Ankara, Auckland, Barcelona, Krakow, Lille, Melbourne, Montreal, Monterrey, and Toronto; they will do so while also trimming down local pollution (Figure 3.6). Conversely, metropolitan regions could lose attractiveness if they continue to pollute, as in the cases of Chicago, Los Angeles, New York, Osaka, Paris, Philadelphia, Seoul and Tokyo, if current trends continue.

Assuming local pollution is related to attractiveness, and the latter associated to population and firm creation, higher incomes, productivity and wages, then an environmental policy at the local level could generate economic gains. In particular, changing the urban structure by increasing cities' density and intensifying the use of public transportation may induce both improvements in attractiveness – and therefore economic performance – and in cities' responsiveness to climate change. As will be developed below, densification policies to respond to climate change can take the form of removing tax and development disincentives

Figure 3.4. **Trends in carbon emissions under a 450 ppm urban climate policy scenario compared with the baseline**

in the urban core, actively pursuing compact spatial form, and increasing mass transit networks and urban amenities in areas targeted for higher-density growth. These issues should be at the heart of the ongoing debate about a green growth strategy.

Other benefits of urban climate policies

Additional local benefits resulting from emissions reductions and climate adaptation policies may also be partly responsible for a potential positive relationship between economic growth and GHG emissions reduction at the metropolitan regional level. These benefits can be grouped into four categories:

- i) Public health improvements.
- ii) Cost savings and increased efficiency.
- iii) Energy security and infrastructure improvements.
- iv) Improved quality of life.

Table 3.1. **GDP changes under implementation of alternative climate policy packages**

OECD				
Discount rate (%)	Stabilisation target: 450 ppm (IPCC scenario III, 2007)		Stabilisation target: 410 ppm (IPCC scenario II, 2007)	
	Carbon price (%)	Carbon price + Urban spatial policy (%)	Carbon price (%)	Carbon price + Urban spatial policy (%)
1	-0.05	-0.04	-0.91	-0.85
3	-0.16	-0.15	-0.84	-0.67
7	-0.34	-0.33	-0.72	-0.37

World		
Discount rate (%)	Stabilisation target: 450 ppm (IPCC scenario III, 2007)	Stabilisation target: 410 ppm (IPCC scenario II, 2007)
	Carbon price (%)	Carbon price (%)
1	-0.88	-4.16
3	-1.01	-3.62
7	-1.15	-2.95

Notes: For a given discount rate *r*, GDP losses are actualised starting from 2010, year at which the urban densification policy is expected to be set in place.

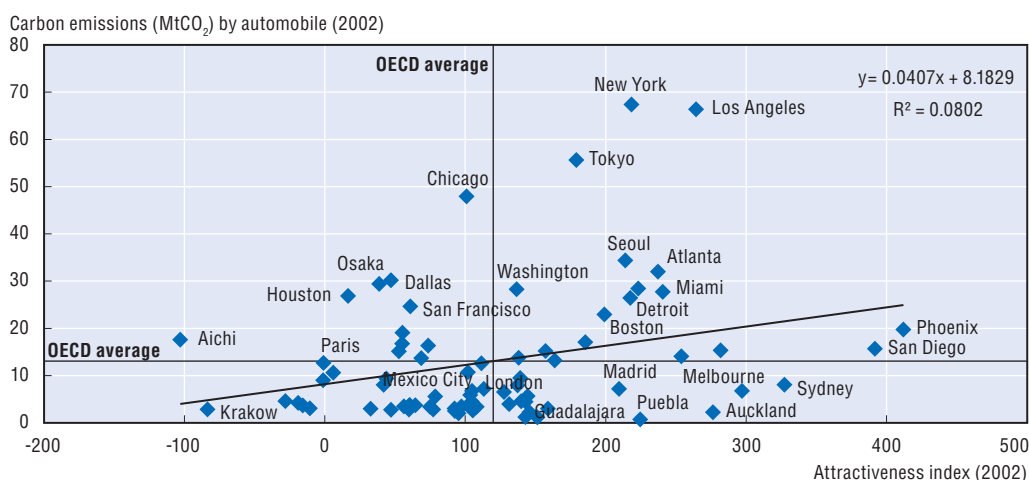

Actualised GDP losses are computed by making use of the standard formula: $\sum_{t=2010}^{2050} \frac{GDP_t}{(1+r)^{t-2010}}$

Note that with high discount rates both losses and gains, in the long term, yield low discounted values. In a scenario in which losses take place at the beginning of the period and gains at the end (such as in Figure 3.3) then the discounted cumulated losses are higher than the discount rate.

Each of these categories of benefits represent gains beyond those directly related to reduced GHG emissions or protection against climate change impacts. Table 3.2 provides an overview of some of the main co-benefits of mitigation policy in urban areas. The non-climate benefits of certain climate change policies are strong enough to warrant their implementation regardless of their impact on mitigating or adapting to climate change. In these cases they are considered “no-regrets” strategies (Hallegatte et al., 2008).

StatLink <http://dx.doi.org/10.1787/888932342430>

Table 3.2. **Related aims and co-benefits of sector policies to reduce GHGs at urban scale**

Sector	Climate policy aims and benefits	Other (non-climate change) benefits
Electricity production and industrial energy use	Encourage energy efficiency and fuel switching from coal and oil to low or no-emission energy sources, such as combined heat and power, renewable energy to reduce CO ₂ emissions.	Improve urban air quality and limits regional SO _x and NO _x air pollution, preserve water quality, increase energy security, all of which can deliver local benefits.
Residential and commercial energy: buildings, office equipment and appliances	Lower energy use in housing and household services, reduce CO ₂ emissions.	Lower investment costs for energy suppliers and possibly smooth load; lower operating costs for commercial entities and consumers and avoids regional air pollution from (unnecessary) electricity and/or heat generation; improve comfort and affordability; raise energy security.
Transport	Raise the efficiency and emission performance of vehicles and manage demand by encouraging use of less carbon-intensive modes of transport (e.g. public transit and bicycling), reduce CO ₂ and possibly other GHG emissions.	Lower congestion in cities and reduce harm to human health from urban air pollution; lower dependency on oil imports to raise energy security. However, co-costs may also exist e.g. increased diesel fuel use lowers CO ₂ but increases particulates, which have human health risks; also catalytic converters lower NO _x emissions but raise N ₂ O and CO ₂ emissions.
Waste	Minimise waste, increase recycling and material efficiency in production and packaging, reduce CH ₄ emissions.	Limit needs for costly and unsightly landfilling; improve economic performance.

Mitigating greenhouse gas emissions provides public health benefits by reducing many dangerous air pollutants (OECD, 2008a), making improved public health an important co-benefit of efforts to reduce GHG emissions in metropolitan regions. Indeed, reduction in urban air pollution is an important component of many national estimates of climate change

mitigation co-benefits (Cifuentes, 1999; Davis *et al.*, 2000; and Kunzli *et al.*, 2000). GHG emissions reductions may benefit human health to such a degree as to offset in large part the local costs of emissions reduction (OECD, 2001; Davis *et al.*, 2000; and IPCC, 2007).

Policies to reduce GHG emissions through increasing energy efficiency can also result in widespread benefits by significantly reducing energy costs for business, consumers and governments. Initiatives to improve building energy efficiency are examples of no-regrets strategies because the energy savings achieved can compensate for the initial investment costs in as little as a few years (Hallegatte *et al.*, 2008). Policies to reduce the amount of energy already going to waste in public buildings can therefore be cost-neutral if their implementation costs are compensated over time.

Both mitigation and adaptation policies can improve the security of local infrastructure and public services. Policies to mitigate greenhouse gases improve national security through reducing dependency on foreign energy sources and by reducing the risks involved in transporting highly combustible fossil fuels around the world (Schellnhuber *et al.*, 2004). Adaptation measures can also improve the security of an area's energy supply. For example, improving the resilience, efficiency and redundancy of energy supply networks protects against interruptions in electricity service during extreme heat events and also reduces the risk of shortfalls (peak demand outstripping supply) or intentional attacks on the system. Similarly, some infrastructure to protect coastal cities from storm surge and flood risks can be economically justified even at current sea levels (Hallegatte *et al.*, 2008).

Many of the measures that mitigate climate change and that help adapt to its effects also make cities more liveable and therefore potentially more competitive. For instance, cities that reclaim land in flood plains as part of adaptation plans can make this land available to the public as parks or recreational land. This provides an amenity to residents, removes buildings and other infrastructure from flood plains, reduces the urban heat island effect, helps control downstream flooding, provides habitat for animals, and limits water pollution by slowing storm water runoff into large bodies of water. Efforts to reduce personal vehicle use and increase use of mass transit can improve public safety and reduce traffic congestion and noise (Hallegatte *et al.*, 2008).

Adaptation to climate change and mitigation of climate change can also be complementary strategies. Adaptation focuses on expanding the ability to cope with changes in climate, whereas mitigation focuses on reducing the amount of change through reducing emissions or removing greenhouse gases from the atmosphere through sequestration. In choosing a portfolio of mitigation and adaptation measures, it may be necessary to make investment trade-offs between them. However, adaptation and mitigation can go hand in hand, for example when developing a decentralised energy system based on locally available energy sources. Here, GHG emissions may be lower, as may be the vulnerability to large-area outages from severe weather impacts.

Synergies between policies to reduce GHG emissions and adapt to expected climate change impacts are particularly important at the urban level. For example, efforts to reduce building energy demand for cooling can also reduce urban heat island effects and prevent electricity shortfalls and blackouts during extreme heat events. On the local level, adaptation and mitigation policies are deployed through the same policy sectors, including land-use planning, transportation, and building sectors, as opposed to the global scale, where mitigation and adaptation goals are designed separately. This synergy presents opportunities to design urban mitigation and adaptation policies within a consistent framework (Hallegatte *et al.*, 2008).

Notes

1. The baseline scenarios for both the IMACLIM-R and the OECD ENV-Linkages models, were made consistent through comparable exogenous assumptions on demographic trends, labour productivity, GDP trends (as a proxy for the intensity of economic activity), fossil energy prices, energy intensity of the overall economy and carbon tax trajectories.
2. Densification indicates policies that increase the number of people per km² in a given urban area. These include restrictive and enabling policies. The former actively pursue densification through policies such as green belts, whereas the latter are those that allow activity to be drawn to the core, such as public transportation systems or the elimination of distortions in the market such as taxes for deconcentration.
3. Such a road toll reduces average rather than marginal commuting costs by car (see Henderson, 1974, for the underlying economics of road pricing mechanisms).
4. Note that, in the IMACLIM-R model, the explicit representation of technologies through reduced forms of technology-rich bottom-up sub models allows for an explicit description of agents' decisions that drive the pace and direction of technical change. Moreover, consumption and investment choices in IMACLIM-R are driven by agents' imperfect foresight and explicit inertias on the renewal of equipments and technologies. The combination of these two features is the underlying explanation for moderate carbon abatement costs in IMACLIM-R's policy scenarios when compared to those in other general equilibrium models.
5. Note that a 450 ppm CO₂ scenario roughly corresponds to a 530-550 ppm of all GHG scenario.
6. This is the result for the OECD using the highest discount rate (7%) It is the difference between -0.72% with carbon prices alone and -0.37% with densification added.

ANNEX 3.A1

Computable General Equilibrium Model of Cities and Climate Change: IMACLIM-R and OECD Metropolitan Database

The model and methodology

Approach and capabilities of the model

Our methodology is based on a model that takes into account patterns in OECD metropolitan regions and the feedback mechanisms that can take place between cities and more aggregate dimensions of the economy. Thus, the *OECD Metropolitan Database* is used to model the behaviour of cities through a general equilibrium model that allows for the interaction of such metropolitan regions and the national macroeconomic activity as well as carbon emissions affecting climate change. Understanding those feedback mechanisms is crucial to better inform on long-run trends of aggregate indicators of local and global economic development that are relevant for policy scenario analysis.

The model that is described in this paper yields information on the spatial and economic dimensions of the metropolitan regions such as: i) the social and economic aspects of the spatial structure of the metropolitan regions; ii) supply-side behaviour of the metro-regional economies; and iii) demand-side behaviour of the metro-regional economies. These dimensions of the urban economy allow the construction of an attractiveness indicator for metropolitan regions; differences in such attractiveness will determine the long-run spatial and economic development patterns of the 78 metropolitan regions, largely based on firms' migration decisions.

This model also has the capacity to predict the potential impacts of certain policies at the metropolitan region scale on energy consumption, carbon emissions and economic growth. Our analysis aims at comparing the impact of alternative policy measures at the metro-regional level on core economic and environmental variables. In terms of policy implications, the lessons emerging from the comparative analysis could provide useful information on the potential impact of alternative settings on carbon emissions. The modelling analysis can also be seen as a useful base for further studies of OECD metropolitan regions. To the best of our knowledge, studies combining the theoretical modelling approach and the empirical dynamic computable general equilibrium technique to the relationship between spatial development of metropolitan regions, location choices, energy consumption pathways and climate change are not available.

The model

In our model, the world is composed of many macro-regions each of which can be seen as a mass of metropolitan regions. We assume that each metropolitan region is monocentric and axi-symmetrical spreading along an one-dimensional space $x \in [-d; d]$, where d is the overall city size. Consistent with the traditional approach to urban and regional economics since von Thünen (1966), the central business district (CBD), situated at the origin $x = 0$, is the location where firms choose to distribute once they locate in the metropolitan region. All economic activities take place in the j -CBD, whereas the urban population is distributed within circular peripheral areas surrounding it. In our economy three types of decision makers exist: governments, producers, and consumers. We assume that the government chooses housing policies that maximise the utility of the representative consumer. Profit-maximising firms do not consume land, while utility-maximising workers do. Urban workers settled at a certain point x of d consume $\lambda_j(x)$ units of land and commute a distance x to the CBD. The number of urban workers L_j is given by:

$$L_j = \int_{0 \leq x \leq d} \frac{dx}{\lambda_j(x)} \quad (1)$$

At land market equilibrium, workers are indifferent between any x -location around the CBD of metropolitan region $j \in J$. This comes down to assuming that all people living inside each peripheral ring at each point x face identical external costs. More specifically, the interplay between different commuting costs (based on the distance between each individual's residential place and the CBD, where jobs and all varieties of the differentiated goods are available) and housing costs (being heterogeneous the value and the consumption of land throughout the periphery) are homogenous within each peripheral ring.

Governments own the available land and determine the spatial distribution of housing supply. Hence, heterogeneity of density within the metropolitan region does not result from households' preferences over the available land but is rather exogenously set. We take the trend for the density function $\lambda_j(x)$ as given and choose a power functional form for the sake of simplicity.

$$\lambda_j(x) = \lambda_j^* x^\xi, \text{ with } 0 \leq \xi \leq 1^1 \quad (2)$$

As in Murata and Thisse (2005), each urban worker supplies one unit of labour. Considering unitary commuting costs $\theta_j \geq 0$ in the iceberg form in line with Samuelson (1954),² the effective labour supply of a worker living in the urban area at a distance x from the CBD is:

$$s_j(x) = 1 - 2\theta_j x, \text{ with } -d_j \leq x \leq d_j \quad (3)$$

Condition: $\theta_j \leq \frac{1}{2d_j}$ ensures positive labour supply. The total effective labour supply throughout the urban area is therefore:

$$S_j = \int_{-d_j \leq x \leq d_j} \frac{s_j(x)}{\lambda_j(x)} dx = \frac{2d_j^{1-\xi}}{\lambda_j^*(1-\xi)} \left(1 - 2\theta_j \frac{1-\xi}{2-\xi} d_j \right) \quad (4)$$

whereas the total potential labour supply is given by:

$$L_j = \int_{-d_j \leq x \leq d_j} \frac{1}{\lambda_j(x)} dx = \frac{2d_j^{1-\xi}}{\lambda_j^*(1-\xi)} \quad (5)$$

Letting w_j be the wage rate firms pay to workers to carry out their activity within the j -urban area, commuting costs CC_j faced by one worker in the metropolitan region j result from the losses of effective labour. Combining (4) and (5), we obtain:

$$CC_j = \frac{(L_j - S_j)w_j}{L_j} = \frac{2}{\lambda_j^*(1-\xi)} \frac{1-\xi}{2-\xi} \theta_j d_j \quad (6)$$

We normalise at zero the rent value of the land located at the edges of the city: $R_j(d_j) = 0$. Given that all urban workers are identical from a welfare perspective, using (3) the value of commuting costs $2\theta_j x$ and rent costs $R_j(x)$ is the same throughout the urban city. Precisely:

$$2\theta_j d_j w_j + \lambda_j(x) R_j(x) = s_j(d_j) w_j + 0 = s_j(-d_j) w_j + 0 = (1 - 2\theta_j d_j) w_j \quad (7)$$

From (7), the equilibrium land rent is simply derived, as follows:

$$R_j(x) = \frac{2\theta_j (d_j - |x|)}{\lambda_j(x)} w_j \quad (8)$$

In order to understand how the land rent is distributed among urban workers by the local government, we first calculate the aggregated land cost by integrating $R_j(x)$ over distance x that represents the available urban land, and then divide the resulting figure by the labour force that is active in the city:

$$RC_j(x) = \frac{\int_{-d_j \leq x \leq d_j} \lambda_j(x) R_j(x) \frac{1}{\lambda_j(x)} dx}{L_j} = 2\theta_j w_j \frac{1}{2-\xi} \quad (9)$$

Combining (6) and (9) gives $\frac{CC_j}{RC_j} = 1 - \xi$ which determines the distribution of external costs over commuting and housing: the lower ξ , the more commuting costs are relatively important. From each labourer's income, an amount: $CC_j + RC_j = ECL_j$ is deduced as compensation to live in the urban area. This amount is expected to affect consumers' purchasing power I_j .

Consumption

We consider a macro-regional economy to be comprised of a mass of metropolitan regions (labelled $j = [1; J]$), including two sectors, one composite sector D of the IMACLIM-R manufacturing-plus-service type taking place in a j -metro-regional agglomeration, and one traditional sector F that is active in the non-metro-regional land. We assume that the many firms of the manufacturing-plus-service type produce each one variety (labelled $I = [1; N]$) of one type of the differentiated good q under increasing returns to scale. Therefore, the number of available varieties in each metropolitan region j , $n_j \in N$, is equal to the number of firms that are active in the same metropolitan region. The traditional good is produced under Walrasian conditions (constant returns to scale and perfect competition) and can be freely traded across metropolitan regions. At any time, by assuming the well-known iceberg structure for transport costs (Samuelson, 1952), any variety of the composite good can be traded between two regions. Transportation costs are zero for intra-regional shipment of both goods. We extend the standard NEG literature (Krugman, 1991) by tracking bilateral flows for the mass of metro-regional agglomerations, so that a quantity $c_{jk}(i)$ of a variety produced in metropolitan region j is consumed in k and purchased at a price p_{jk} . We define a

price index P_j of the composite good available in j in order to be able to treat the various products as a single group.

$$P_j = \left[\int_{i=1}^{n_j} p_{ij}(i)^{1-\varepsilon} di + \int_{k \neq j} \int_{i=1}^{n_k} p_{kj}(i)^{1-\varepsilon} didk \right]^{\frac{1}{1-\varepsilon}} \quad (10)$$

Here $\varepsilon > 1$ is the elasticity of substitution between varieties. The economy employs a unit mass of mobile workers L wherever they are employed. Workers (L) are both input production factors and output end-users. Given a certain net income γ_j , individuals should decide allocating over the consumption of the above described differentiated good D (produced in the metropolitan regions), and a “traditional” good F (freely traded and purchased at a homogenous price p_F). We consider that households that reach identical welfare levels and bare identical external costs ECL_j stemming from being located in the j -metropolitan region (see equation [7]). Given individual’s utility U_j defined over the disposable income γ_j for consumption in each j , welfare maximisation behaviour imposes:

$$\max U_j = U_j[D_j(\gamma_j), F_j(\gamma_j)] \quad (11)$$

For the sake of simplicity, we choose a Cobb-Douglas functional form for the utility function:

$$U_j = (D_j)^\beta (F_j)^{1-\beta} (Z_j)^{-\zeta} \quad (12)$$

where, $Z_j = k_j Q_j = k_j n_j q_j$ captures the negative environmental externalities associated with production Q_j via a j -specific coefficient k . The intensity of the environmental burden is measured by the parameter ζ . Price and utility homogeneity throughout the j -metropolitan region impose that aggregate consumption of the composite good is independent on the distance x from the j -core. The constant-across-metropolitan region sub-utility from aggregate consumption of all the varieties composing the manufacturing good is:

$$D_j = \left[\int_{i=1}^{n_j} c_{ij}(i)^{\frac{\varepsilon-1}{\varepsilon}} di + \int_{k \neq j} \int_{i=1}^{n_k} c_{kj}(i)^{\frac{\varepsilon-1}{\varepsilon}} didk \right]^{\frac{\varepsilon}{1-\varepsilon}} \quad (13)$$

The representative consumer has to satisfy the following budget constraint:

$$\int_{i=1}^{n_j} p_{ij}(i) c_{ij}(i) di + \int_{k \neq j} \int_{i=1}^{n_k} p_{kj}(i) c_{kj}(i) didk = \gamma_j \quad (14)$$

where γ_j is the net disposable income for consumption, already discounted from external costs for workers ECL_j (see equation [7]). Maximising utility given in (12) subject to (14) gives the aggregate demand in metropolitan region j for the variety i produced in metropolitan region k :

$$c_{kj}(i) = L_j \gamma_j \frac{(p_{kj})^{-\varepsilon}}{(P_j)^{1-\varepsilon}} \quad (15)$$

Production

All firms producing in a given metropolitan region j incur the same production costs and rely upon the same capital and labour as spatially mobile input factors. We consider labour as subject to external economies of scale resulting from improved production process through some metropolitan region-specific technology spillover, as follows:

$$l_j = \frac{l_{j,0}}{n_j^\alpha} \quad (16)$$

where l_j is the effective unitary labour input requirement for production, n_j is the given number of active firms in region j , α is a parameter that captures the non linearity of the external agglomeration effect (Fujita and Thisse, 1996; Grazi et al., 2007), and $l_{j,0}$ is the agglomeration-specific unitary labour input requirement for production in absence of agglomeration effects ($\alpha = 0$).

Due to the fixed input requirement, the amount of productive capital in metropolitan region j , X_j is proportional to the number of domestic firms, n_j :

$$X_j = xn_j \tag{17}$$

Firms of the above type find it profitable to join a certain metropolitan region j to benefit from a specialised labour market. This brings about differences in terms of labour productivity between producing inside and outside the metropolitan region. To avoid all firms concentrating in the same place because of absent specific differentiation, we introduce inherent reasons for differential location choices. We therefore assume that firms choose to locate according to the trade-off between production benefits and costs that are specific of the metropolitan region j . Concerning the former, they take the form of heterogeneous labour productivity across different metropolitan regions (that is $l_j \neq l_k$), whereas the latter (i.e. production costs) are indirectly captured by the different labour costs (namely, the wage rate w_j) firms face across the different metropolitan regions to compensate workers for the metropolitan region-specific external costs. Letting r_j and w_j the unitary returns of, respectively, capital X_j and labour l_j , the total cost of producing q_j for a firm $I \in n_j$ in region j is expressed as:

$$TC(i) = r_j x + l_j w_j q_j(i) \tag{18}$$

Given its monopoly power, it is clear that each firm acts to maximise profit:

$$\pi_j(i) = p_j q_j(i) - [r_j x + l_j w_j q_j(i)] \tag{19}$$

In order to integrate the spatial dimension into the model, trade is allowed between the metropolitan regions. We use the iceberg form of transport costs associated with trade of composite goods (Samuelson, 1952). In particular, if one variety i of manufactured goods is shipped from metropolitan region j to metropolitan region k , only a fraction will arrive at the destination, the remainder will melt during shipment. This means that if a variety produced in location j is sold in the same metropolitan region at price p_{jj} , then it will be charged in consumption location k at a price:

$$p_{jk} = T_{jk} p_{jj} \tag{20}$$

where $T_{jk} > 1$ captures the trade cost from metropolitan region j to metropolitan region k .

As already mentioned, the freely tradable traditional good F is produced under constant returns to scale and perfect competition. Letting r_F and w_F be the unitary returns of, respectively, capital X_F and labour l_F , the total cost of producing q_F for a firm settled outside the metro-regional area is expressed as follows:

$$TC_F = (r_F X_F + l_F w_F) q_F \tag{21}$$

In such a perfectly competitive market, the price of the traditional good is obtained directly from marginal production costs:

$$p_F = r_F X_F + l_F w_F \tag{22}$$

Short-run market equilibrium

Given n_j firms operating in the metropolitan region j , the labour-market equilibrium condition posits that the total labour effectively supplied S_j (see equation [4]) is equal to the total labour requirements by production $l_j n_j q_j$:

$$S_j = L_j \left[1 - 2 \frac{1-\xi}{2-\xi} \theta_j d_j \right] = l_j n_j q_j \quad (23)$$

where, we recall, d_j is the size of metropolitan region j , θ_j is the unitary commuting cost in metropolitan region j and $n_j q_j$ is the total domestic production of the composite good.

Moreover, the market clearing condition imposes that all that is produced by firms is also consumed by individuals. Hence, production size $q_j(i)$ of a firm located in region j is as follows:

$$q_j(i) = c_{jj}(i) + \int_{k \neq j} T_{jk} c_{jk}(i) dk \quad (24)$$

For the sake of simplicity and without loss of generality we consider that all varieties are identical. This allows us to drop the notation i for the variety in the remaining analysis.

In particular, the price index in (10) can be re-written as: $P_j = \left[n_j p_j^{1-\varepsilon} + \int_{k \neq j} n_k (T_{kj} p_k)^{1-\varepsilon} dk \right]^{\frac{1}{1-\varepsilon}}$

By plugging (15) into (24), we obtain the equilibrium production of one firm operating in metropolitan region j .

$$q_j = L_j \Upsilon_j \frac{(p_j)^{-\varepsilon}}{(P_j)^{1-\varepsilon}} + \int_{k \neq j} T_{jk} L_k \Upsilon_k \frac{(T_{jk} p_k)^{-\varepsilon}}{(P_k)^{1-\varepsilon}} dk \quad (25)$$

As a consequence of profit maximisation behaviour, firms will enter and exit the manufacturing sector until the point at which profits are zero, as an equilibrium condition of monopolistic competition. Therefore, by substituting (25) into (19) and setting $\pi_j = 0$, the return to capital r_j at equilibrium is straightforwardly obtained:

$$r_j = \frac{(p_j - l_j w_j) q_j}{\chi} \quad (26)$$

Recalling that p_j is the price of a variety i that is both produced and sold in metropolitan region j , under the Dixit-Stiglitz monopolistic market we see that a profit-maximising firm sets its price as a constant mark-up on variable cost by assuming a constant elasticity of substitution (CES), $\varepsilon > 1$:

$$p_j = \frac{\varepsilon}{\varepsilon - 1} \frac{\partial TC_j}{\partial q_j} = \frac{\varepsilon}{\varepsilon - 1} \frac{l_j w_j}{n_j^\alpha} \quad (27)$$

All varieties are sold in the metropolitan region at the same price and no trade costs occur to spatially differentiate the market value of a given variety. It is worth describing what we consider as the wage rate w_j . In our spatial economy, a fraction of the whole available land hosts metro-regional activities. The equilibrium on workers' migration imposes that the utility level *per unit of labour* reached by living within the j -metropolitan regional area is identical to the one achieved within the k -one. This is because certain beneficial effects are expected to be homogeneously faced by individuals as they decide to enter the metro-regional market.

Workers will chose to enter the metro-regional market if the utility they reach there is at least equal to level of (unitary, per unit of work) utility in the outside area, u^* .

$$\frac{(D_j)^\beta (F_j)^{1-\beta} (\kappa_j n_j q_j)^{-\delta}}{l_j n_j q_j} = u^* \quad (28)$$

Our model allows for income distributional effects and assumes that all revenues produced in metropolitan region j are redistributed locally. In other words, the aggregate revenue in metropolitan region j , $L_j \lambda_j$ equals the sum of total wages $l_j w_j n_j q_j$ and return to capital $r_j X_j$: $L_j \lambda_j = l_j w_j n_j q_j + r_j X_j$.³

Utility maximisation under the Cobb-Douglas specification in (1) leads to the following identities between prices and quantities for the two market goods: $P_j D_j = \beta \lambda_j$ and $p_F F_j = (1 - \beta) \lambda_j$. Substituting the two identities into (28) gives the equilibrium wage rate for a worker in metropolitan region j :

$$w_j = u^* \frac{\varepsilon - 1}{\varepsilon \beta^\beta (1 - \beta)^{(1-\beta)}} P_j^\beta p_F^{(1-\beta)} (\kappa_j n_j q_j)^\delta \quad (29)$$

The long-run model

This chapter extends the short-run model so as to address dynamics over time and ensure analytical consistency for inclusion in the IMACLIM-R framework as a specific module accounting for the spatial organisation of the economy at the urban scale. Dynamics in our modelling framework are carried out in two steps.

Spatial disaggregation

We consider the IMACLIM-R static equilibrium at time t . At this time, macroeconomic information at the macro-regional and national levels are disaggregated into a combination of local urban economies where the interactions between economic agents occur in the form developed in the previous sections.

In each metropolitan region j at time t , a fixed number of profit-maximising firms $n_j(t)$ sets prices $p_j(t)$ and quantities $q_j(t)$ to meet households' demand for the composite good D , according to (25) and (27). Labour requirement for production drives population distribution $L_j(t)$ and metropolitan region size $d_j(t)$ through relations (23) and (5), respectively. Consistency between descriptions of the economy at the metro-regional and macro-regional or national scales requires ensuring that the average value of each spatially disaggregated (i.e. metro-regional) variable equals the value of the corresponding aggregate (macro-regional) variable resulting from the IMACLIM-R equilibrium.

Firm mobility

The second step of the module describes firms' location decisions and induced changes in the spatial distribution of firms and productive capital in the national economy. Metropolitan regions differ in labour and infrastructure endowments, captured in the model by labour productivity l_j and unitary commuting costs θ_j , respectively. These j -specificities act as constraints on production expectations (through [18]) and expected capital returns (through [26]), and hence influence the attractiveness of metropolitan regions for productive investment. The attractiveness of metropolitan regions ultimately affects the migration decisions of firms.

Location decisions across the set of available metropolitan regions at time t are taken by firms on the basis of an index of relative attractiveness $a_j(t)$ that accounts for the capital return investors expect to receive from investments in a given metro-regional market. This reflects the active role of shareholders who want to maximise the return to capital, which is *a priori* a cost to firms. The relative attractiveness $a_j(t)$ helps determine the stable spatial distribution of firms across the available metropolitan regions at equilibrium time $t + 1$, $n_j(t + 1)$.

Two types of firms base their location decisions on $a_j(t)$: the existing firms at previous equilibrium time, and the newly created firms. For each of the two groups of firms we are able to establish the stable number of firms at a given equilibrium time.

- i) First, consider the case of two metropolitan regions labelled j and k , with $j, k = (1; 2)$; $j \neq k$. For a generic old j -firm (that is a firm coming from previous equilibrium time and settled in metropolitan region j), the magnitude of the incentive to migrate to k depends on the relative attractiveness of metropolitan region j :

$$m_{j \rightarrow k} = \pm \left| a_k(t) - a_j(t) \right|^{\gamma_1} \left(\frac{1}{\delta_{jk}} \right)^{\gamma_2} \left| \frac{1}{l_k(t) - l_j(t)} \right|^{\gamma_3} \quad (30)$$

where δ_{jk} is the distance between the metropolitan regions j and k , $l_k(t)$ measures the productivity of labour in metropolitan region k , and $\gamma_1, \gamma_2, \gamma_3$ (such that $\gamma_1, \gamma_2, \gamma_3 > 0$ and $\gamma_1 + \gamma_2 + \gamma_3 = 1$) represent the measurement of the relative migration incentive of, respectively, attractiveness, distance, and labour productivity.

Equation (30) writes that a generic j -firm is encouraged to move to k from metropolitan region j if condition: $a_k(t) - a_j(t) > 0$ is verified (as this ensures $m_{j \rightarrow k} > 0$). The magnitude of this incentive is a function of: i) the difference in relative attractiveness between metropolitan regions; ii) the physical distance δ_{jk} between them; and iii) the absolute difference between metropolitan regions in the structure of production, as captured by the labour productivity term $l_k(t) - l_j(t)$. Extending (30) for a more generic application, in which many alternative metropolitan regions are spatially available, the incentive to move to an metropolitan region j from any other k (with $j, k = (1; J)$ and $j \neq k$) is derived as follows:

$$M_j = \mu^M \int_{k \neq j} m_{j \rightarrow k} dk \quad (31)$$

where μ^M is a parameter that homogenises the units of measurement.

- ii) Consider now the case of new firms that are created at the equilibrium time t . They spatially sort themselves across the J metropolitan regions according to the value of relative metro-regional attractiveness. The number of firms created in metropolitan region j is proportional to the emerging force E_j :

$$E_j(t) = \mu^E a_j(t) \quad (32)$$

where μ^E is a parameter that homogenises the units of measurement. Given the economy size at time t , the total number of firms in metropolitan region j at the equilibrium time $t + 1$ results from the interplay between firms' migration decisions from other metropolitan regions and entry of new firms:

$$n_j(t + 1) = n_j(t) + M_j(t) + E_j(t) \quad (33)$$

The absolute attractiveness $A_j(t)$ of a j -metropolitan region is given by the absolute variation of firms between consecutive equilibria, $n_j(t + 1) - n_j(t)$, so that:

$$A_j(t) = M_j(t) + E_j(t) \quad (34)$$

Main results of the model with a climate policy only

Considering the evaluation of possible impacts of local policies, it is important to bear in mind the impacts that a carbon policy alone might entail without the urban module in the IMACLIM-R model. The results in terms of cost effects of implementing a single carbon tax can be expressed as the ratio of GDP under the carbon tax compared to the baseline scenario (no carbon tax). In the first 20 years of the carbon tax implementation period the OECD economy faces significant, yet temporary, losses with respect to the baseline (in

which no tax is put into operation). This is due to the initially strong increase of the price of carbon, which tends to accelerate technical change despite the inertias characterising the renewal of production equipment, technologies and infrastructure. By 2032, the improvement of energy efficiency confirms to be highly beneficial for economic activity, especially because it renders the economy less vulnerable to oil shocks. This is captured by a rapid increase in GDP (Figure 3.A1.1).

Figure 3.A1.1. **Economic impact of a climate policy alone using the baseline scenario**

Ratio of OECD GDP under climate policy to OECD GDP under baseline scenario

Notes

1. Condition $\xi \geq 0$ ensures that $\lambda_j(x)$ is an increasing function, so that the empirical evidence of higher population density in the centre of the city is captured. Condition $\xi \leq 1$ is necessary to have population convergence in (1).
2. Considering different unitary commuting costs θ_j across the agglomerations captures the specificities of each agglomeration in terms of modal shares and transport infrastructures.
3. Note that implicitly, this expression means that the housing rents are also redistributed across households, as they do not appear in the income formation.
